Received July 28, 2003

The synthesis and magnetic properties are reported of two new clusters [Mn10O4(OH)2(O2CMe)8(hmp)8](ClO4)4 (1) and [Mn7(OH)3(hmp)9Cl3](Cl)(ClO4)2 (2). Complex 1 was prepared by treatment of [Mn3O(O2CMe)6(py)3](ClO4) with 2-(hydroxymethyl)pyridine (hmpH) in CH2Cl2, whereas 2 was obtained from the reaction of MnCl2·4H2O, hmpH, and NBu4[MnO4] in MeCN followed by recrystallization in the presence of NBu4ClO4. Complex 1-2py·10CH2Cl2·2H2O crystallizes in the triclinic space group P1̅. The cation consists of 10 MnII ions, 8 μ3-O2− ions, 2 μ2-O− ions, 8 bridging acetates, and 8 bridging and chelating hmp− ligands. The hmp− ligands bridge through their O atoms in two ways: two with μ3-O atoms and six with μ2-O atoms. Complex 2-3Cl·Cl2·H2O crystallizes in the triclinic space group P1̅. The cation consists of four MnII and three MnIII ions, arranged as a Mn6 hexagon of alternating MnII and MnIII ions surrounding a central MnII ion. The remaining ligation is by three μ3-O− ions, three terminal chloride ions, and nine bridging and chelating hmp− ligands. Six hmp− ligands contain μ2-O atoms and three contain μ3-O atoms. The Cl− anion is hydrogen-bonded to the three μ3-O− ions. Variable-temperature direct current (dc) magnetic susceptibility data were collected for complex 1 in the 5.00–300 K range in a 5 kG applied field. The 2M value gradually decreases from 17.87 cm3 mol−1 K at 300 K to 1.14 cm3 mol−1 K at 5.00 K, indicating an S = 0 ground state. The ground-state spin of complex 2 was established by magnetization measurements in the 0.5–3.0 T and 1.80–4.00 K ranges. Fitting of the data by matrix diagonalization, incorporating only axial anisotropy (DŚ2), gave equally good fits with S = 10, g = 2.13, D = −0.14 cm−1 and S = 11, g = 1.94, D = −0.11 cm−1. Magnetization versus dc field scans down to 0.04 K reveal no hysteresis attributable to single-molecule magnetism behavior, only weak intermolecular interactions.

**Introduction**

A wide variety of polynuclear Mn clusters have been synthesized to date with the metal in the oxidation state range of II–IV, including clusters with mixed-valency. These complexes usually contain carboxylate ligands, and they are usually molecular but are sometimes polymeric. Molecular species with metal nuclearities up to 30 have been reported to date. One of our interests in these molecules is the often large ground-state spin (S) that they possess and the resulting possibility that such molecules might function as single-molecule magnets (SMMs). A SMM possesses a significant

energy barrier to relaxation of its magnetization vector, which arises from the combination of a large ground-state spin and a significant magnetooanisotropy of the Ising (easy-axis) type, as reflected by a negative axial zero-field splitting parameter, \( D \). The upper limit of this energy barrier is given by \( S(S^2 - 1/4)D \) for integer or half-integer spins, respectively.\(^{4,5}\) For such reasons, there is a continuing need for new examples of molecular metal species that possess large ground-state \( S \) values.

The present work comprises the synthesis and study of both a \( \text{Mn}^\text{II} \) hmp\(^-\) species and a \( \text{Mn}_{10} \) hmp\(^-\) species, where hmp\(^-\) is the anion of 2-(hydroxymethyl)pyridine and is a N,O bidentate chelate. The hmp\(^-\) chelate has already proven very useful to us in the past for the synthesis of a number of Mn clusters of varying nuclearities. Other than the \( \text{Mn}^\text{II} \) and \( \text{Mn}_{10} \) species to be presented here, it has been used in Mn chemistry for the synthesis of \( \text{Mn}_{10}^\text{II} \), \( \text{Mn}_{12}^\text{II} \) and \( \text{Mn}_{18}^\text{II} \) clusters, which have turned out to be SMMs. The hmp\(^-\) group can be both a chelating and a bridging ligand, the latter by the alkoxide O atom. As a result, we have frequently found that it fosters the formation of high-nuclearity species.

In the present work, the use of hmp\(^-\) in two different reaction systems has led to two new high-nuclearity products, namely, a \( \text{Mn}^{\text{III}}_{11} \) cluster and a \( \text{Mn}^{\text{II},\text{III}}_{12} \) mixed-valence cluster. We describe the syntheses, crystal structures, and magnetic properties of these two species. These products are useful new additions to the growing family of Mn clusters with the hmp\(^-\) chelate and should also prove useful for further synthesis, as recently demonstrated in the use of the \( \text{Mn}_{10} \) complex as a starting material for the synthesis of \( [\text{Mn}_n^- \text{hmp}_2 \text{Cl}_2 \text{O}_4]_k \).\(^{9}\)

**Experimental Section**

All manipulations were performed under aerobic conditions using materials as received. \( [\text{Mn}_7\text{O}_2\text{O}_{2}\text{CMe}_6\text{py}_3]^+\text{ClO}_4^- \) and \( \text{NBu}_4^+\text{MnO}_4^- \) were prepared as described.\(^{10}\)

\[ [\text{Mn}_7\text{O}_2\text{O}_{2}\text{CMe}_6\text{py}_3]^+\text{ClO}_4^- \]

To a stirred, red-brown solution of \( [\text{Mn}_7\text{O}_2\text{O}_{2}\text{CMe}_6\text{py}_3]^+\text{ClO}_4^- \) (2.09 g, 2.40 mmol) in MeCN (50 mL), an excess of \( \text{NBu}_4^+\text{MnO}_4^- \) (0.85 g, 2.5 mmol) was added, and the solution was filtered. Hexanes (5 mL) were added to the filtrate, and the solution was maintained undisturbed in a sealed flask. Brown crystals of \( 2\text{CH}_2\text{Cl}_2\text{H}_2\text{O} \) slowly grew over 2 weeks, and they were collected by filtration, washed with hexanes, and dried in air. The yield was 30%. Anal. Calcd for \( [\text{Mn}_7\text{O}_2\text{O}_{2}\text{CMe}_6\text{py}_3]^+\text{ClO}_4^- \) \( \times 2\text{H}_2\text{O} \): C, 46.73; H, 2.76; N, 10.46; Cl, 15.16. Found: C, 46.7; H, 2.8; N, 10.4; Cl, 15.2.

\[ [\text{Mn}_7\text{O}_2\text{O}_{2}\text{CMe}_6\text{py}_3]^+\text{ClO}_4^- \]

A selective search of a limited hemisphere of reciprocal space revealed no symmetry among the observed intensities. The choice of space group \( P1 \) was later proven correct by the successful solution of the structure. Following complete intensity data collection (+h+k+l, t), data processing produced a unique set of 8565 intensities and gave a residual of 0.058 for the averaging of the 2-fold redundant data. No correction was made for absorption.

The structure was solved using a combination of direct methods (MULTAN78) and Fourier techniques and refined by full-matrix least-squares analysis. The \( \text{Mn}_{10} \) cation lies on a crystallographic center of symmetry. In addition to the half cation, the asymmetric unit contains two \( \text{ClO}_4^- \) anions, one of which is reasonably well-ordered and one that has approximate 2-fold disorder. Also present are a well-ordered molecule of pyridine solvent, five disordered \( \text{ClO}_4^- \) anions, and a \( \text{Cl} \) atom on a \( \text{CH}_2\text{Cl}_2 \), which was modeled as a water molecule and which refined to an occupancy of 30%. Non-hydrogen atoms of the cation, the anions, and the pyridine molecule were refined with anisotropic displacement parameters; the remaining non-hydrogen atoms were refined with isotropic thermal parameters. Hydrogen atoms were included in fixed, calculated positions for the cation and the pyridine molecule, with thermal parameters fixed at one plus the isotropic thermal parameter of the carbon atom to which they are bonded. The final \( R(F) \) was 0.084 for 798 total variables using all of the unique data. Data having \( F < 3\sigma(F) \) were given zero weight. The

a Including solvate molecules. b Graphite monochromator. c R = Σ|Fo| − |Fc|/Σ|Fo|; wR2 = Σ[w(Fo−Fc)²]/Σ(w|Fo|²)1/2, where w = 1/[σ²(Fo)+0.0004p²] and p = |Fo|/2[Fc]3/2.

largest peak in the final difference Fourier map was 1.96 e Å−1 in a disordered solvent molecule, and the deepest hole was −1.02 e Å−3.

Data for complex 2·3CH3Cl2·H2O were collected at −80 °C on a Siemens SMART PLATFORM equipped with a charge coupled device (CCD) area detector and a graphite monochromator utilizing Mo Kα radiation (μ = 0.710 73 Å). Cell parameters were refined using up to 8192 reflections. A full sphere of data (1850 frames) was collected using the ω-scan method (0.3° frame width). The first 50 frames were re-measured at the end of data collection to monitor instrument and crystal stability (maximum correction on I was <1%). Absorption corrections by integration were applied based on indexed measured crystal faces.

The structure was solved by the direct methods in SHELXTL5 and refined using full-matrix least-squares analysis.12 The non-hydrogen atoms were refined anisotropically, whereas the hydrogen atoms were included in fixed, calculated positions with thermal parameters fixed at one plus the isotropic thermal parameter of the carbon atom to which they are bonded. The hydrogen atoms on the hydroxyl groups were located in a difference Fourier map and refined freely. The asymmetric unit contains the Mnh cation, a ClO4 anion, a disordered solvent molecule, and the deepest hole was −1.02 e Å−3.

The asymmetric unit contains the Mn7 cation, a ClO4 anion, three CH2Cl2 molecules, one of which has one of its Cl atoms disordered over two positions, and a water molecule whose H atoms were located in a difference Fourier map but were refined as riding on its O atom. A total of 932 parameters were refined in the final cycle of refinement on F2 using 8409 reflections with I > 2σ(I) to yield R1 and wR2 values of 3.19% and 9.06%, respectively.

Crystallographic data and structure refinement details for both complexes are listed in Table 1.

Other Measurements. Elemental analyses were performed by Atlantic Microlab, Inc. (Norcross, GA) and by the in-house facilities of the Chemistry Department, University of Florida. IR spectra were recorded as Nujol mulls with a Nicolet 520 FT-IR spectrometer or as KBr disks using a Nicolet Nexus 670 spectrophotometer. Variable-temperature, solid-state direct current (dc) magnetic susceptibility data down to 5.00 K were collected on a Quantum Design MPMS-XL SQUID magnetometer equipped with a 7 T dc magnet at the University of Florida. Diamagnetic corrections were applied to the observed paramagnetic susceptibilities using Pascal’s constants. The dc measurements below 1.80 K were performed on single crystals using an array of micro-SQUIDS.13

Results and Discussion

Synthesis. The initial reaction explored was that between 1.5 equiv. of hmpH and [Mn3O(O2CMe)6(py)3](ClO4) in CH2Cl2. Such reactions between a triangular Mn3 species containing three MnIII ions and a chelating ligand have been previously explored by us for a wide variety of bidentate chelates, the first one employed being 2,2′-bipyridine (bpy), which resulted in formation of Mn6 complexes with the [Mn3O2] butterfly-like core.14 For the reaction with hmpH, the product proved to be the Mn10 complex 1. This species contains 10 MnIII ions, and thus there was no change to the Mn oxidation level compared to the starting Mn3 complex. However, the yield of 1 was small (20%), and it is likely, as with many other reactions in MnIII chemistry, that the reaction solution contains a complicated mixture of several species in equilibrium, with factors such as relative solubility, lattice energies, crystallization kinetics, and others determining the identity of the isolated product. Along these lines, it is worth noting that the use of the benzoate analogue [Mn3O(O2CPPh)6(py)3](ClO4) instead of [Mn3O2CMe6(py)3](ClO4) in an otherwise identical reaction system did not lead to isolation of the benzoate analogue of 1 but instead led to crystallization of [Mn3O2(C6H4(O2CMe)6)(MeCN)2] containing 4MnIII, 2MnII, and no bound hmpH groups. This and similar hexanuclear species differing in the identity of the bound neutral ligands have been previously observed and are common products at this oxidation level with benzoate groups.15

A few other Mn10 complexes have been reported in the literature. Addition of NMe4OH to a solution of MnCl2·4H2O and 2,2′-biphenol (biphenH2) in EtOH resulted in the formation of (NMMe4)4[Mn10(biphen)O2Cl2]. The molecule has a Mn6hMn4iii formulation, and single-crystal EPR data gave S = 12 and D = −0.035 cm−1.16 Another Mn10 cluster was formed from the dissolution of [Mn2O2(CPPh)3(C6H4(bpy))2](picH) (picH is picolinic acid) in MeCONMe2 and CH2Cl2 in the presence of picH, which gave [Mn10O2(C2CPPh)6(pic)3] possessing an S = 0 ground state.17 The complex (NEt4)2[Mn10O4Cl8{(OCH2)3(CMe)}6], obtained from the use of a triol chelate, contains Mn3−5Mn65 with an edge-sharing bi-octahedral Mn10 topology, but its ground-state spin value was not reported.18 Finally, the MnIII,MnIV complex [Mn10O4(3N(CH2CH2NH2)2)]6 is particularly relevant to the

present work, even though the oxidation level is very different, because it contains a similar central Mn₆ unit with an overall layered structure. Again, the ground state has not been reported.

Complex 2 was obtained from the comproportionation reaction between MnCl₂ and NBu₄MnO₄, in a 3:2 ratio in the presence of hmpH. This ratio on paper gives an average Mn oxidation state in solution of MnIV, but again, the solution likely contains a complicated mixture. Complex 2 (4MnII, 3MnIII) was isolated from this solution in 30% yield. In an attempt to increase the yield of the product, the MnII/MnO₄⁻ ratio was increased to that which would give an average of +2.4, as found in 2, but this resulted in no formation of this product.

The reaction was performed in the presence of NBu₄ClO₄ to afford the ClO₄⁻ salt of this Mn₇ cation. We had previously isolated the same cation but as the mixed cation and anion salt (NEt₄)[Mn₇(OH)₃(hmp)₉Cl₃](Cl)(MnCl₄), which was reported in the preliminary communication of this work. However, the presence of the paramagnetic [MnCl₄]²⁻ counterion was undesirable in the magnetic characterization of the Mn₇ species, and so the ClO₄⁻ salt was targeted and successfully prepared.

A few other Mn₇ complexes have also been reported previously. The reaction between MnCl₂, NaOMe, dibenzoylmethane (dbmH), and oxygen in anhydrous MeOH was found to yield [Mn₇(OMe)₁₂(dbm)₆]. This complex contains MnII,MnIII, and possesses an S = 17/2 ground state. The

Figure 1. ORTEP representation and stereopair of the centrosymmetric cation of complex 1 at the 50% probability level. Hydrogen atoms have been omitted for clarity.

complex $[\text{Mn}_7(\text{teaH}_2)\text{tea}_3](\text{ClO}_4)_2$ (teaH$_3$ is triethanolamine)$^{22}$ contains a Mn$^{II}$$\cdot$Mn$^{III}$ core very similar to that of 2, with an essentially identical Mn$_7$ topology. Magnetic susceptibility measurements concluded that the ground state is $S = 11$. Finally, the complex $(\text{NEt}_4)[\text{Mn}_7\text{O}_4(\text{O}_2\text{CMe})_{10}(\text{dbm})_4]$ has an extended Mn$_7$ topology and an $S = 4$ ground state.$^{23a}$

The Mn$_{10}$ and Mn$_7$ nuclearities of 1 and 2 may be put into context by noting that the largest molecular Mn cluster currently known is $[\text{Mn}_{30}\text{O}_{24}(\text{OH})_8(\text{O}_2\text{CCH}_2\text{Bu}_3)_3(\text{H}_2\text{O})_2(\text{MeNO}_2)_4]$,$^{23b}$ followed by $[\text{Mn}_{26}\text{O}_{16}(\text{OH})_{10}(\text{OMe})_6\text{F}_{10}(\text{bta})_2(\text{btaH})_2(\text{MeOH})_{13}(\text{H}_2\text{O})]$, where btaH is benzotriazole.$^{23c}$

**Description of Crystal Structures.** Labeled ORTEP$^{24}$ plots of complexes 1 and 2 are presented in Figures 1 and 2, respectively. Selected bond lengths and angles are listed in Tables 2 and 3, respectively.

![Figure 1](image1.png)

**Figure 1.** ORTEP representation and stereopair of the cation of complex 1 at the 50% probability level. Hydrogen atoms have been omitted for clarity.

Complex 1·2py·10CH$_2$Cl$_2$·2H$_2$O crystallizes in the triclinic space group $P\overline{1}$ with the Mn$_{10}$ cation lying on a crystallographic center of symmetry. The cation consists of 10 Mn$^{III}$ ions, 4 $\mu_2$-$\text{O}^{2-}$ ions, 2 $\mu_3$-$\text{OH}^-$ ions, 8 bridging acetate groups, and 8 bridging hmp$^-$ ligands. There are two types of hmp$^-$ ligands: six containing $\mu_2$-$\text{O}$ atoms and two containing $\mu_2$-$\text{O}$ atoms, involving O(16) and O(16$'$). All Mn atoms are six-coordinate and experience a Jahn–Teller axial distortion (elongation), as expected for a high-spin d$^4$ ion in near-

octahedral geometry. The Mn$^{III}$ oxidation states were confirmed by bond valence sum calculations. The two OH$^-$ oxygen atoms are assigned as O(6) and O(6$'$), based on the bond valence sum calculations and also on the presence of an O–H⋯N hydrogen-bonding contact with the pyridine molecules of crystallization in the lattice (O⋯N = 2.614 Å).

The [Mn$_{10}$O$_{4}$O(OH)$_{2}$O$_{2}$CMe)$_{8}$]$^{4-}$ core is relatively planar, with the inner core of six Mn atoms (Mn(1), Mn(1$'$), Mn(2), Mn(2$'$), Mn(3), and Mn(3$'$)) almost perfectly so (Figure 3, top). This inner unit can be described as four face-sharing MnO$_{4}$ partial cubane (i.e., cuboidal) units. The side view in Figure 3 also emphasizes that the core is composed of alternating layers of O, Mn, and O atoms. This is similar to the Mn and O arrangements in the AX$_{2}$ layered structures of the minerals lithiophorite (Al, Li)MnO$_{2}$OH$_{2}$ and chalcophorite, ZnMn$_{2}$O$_{3}$-3H$_{2}$O. This type of layered structure has also been seen in the cluster [Mn$_{2}$O$_{2}$O(OMe)$_{6}$O$_{2}$CCH$_{2}$Bu$_{3}$O(H$_{2}$O)$_{1}$], composed of Mn$^{III}$Mn$^{IV}$$_{2}$.

It is interesting that the $\mu_{3}$-OH$^-$ ions bridge very asymmetrically. Thus, Mn(1)–O(6$'$) and Mn(2)–O(6$'$) are 1.873(6) and 1.875(6) Å, respectively, whereas Mn(1)–O(6) is much longer at 2.314(6) Å. This is the result of O(6) lying on the Jahn–Teller (JT) elongation axis of Mn(1). Similarly, the alkoxide O atom O(16) of the triply bridging hmp$^{-}$ group also bridges asymmetrically as a result of it lying on the JT elongation axes of both Mn(2) and Mn(3). Bond lengths to these Mn atoms are 2.205(6) and 2.253(6) Å, respectively, whereas Mn(1)–O(16) is 1.987(6) Å. As a result of the JT-elongated bonds Mn(1)–O(6), Mn(2)–O(16), and their symmetry-related partners all being parallel, the inner, planar Mn6 core of 1 can reasonably be described as two linear and planar [Mn($\mu$-O):Mn($\mu$-O):Mn] units held together by the above JT-elongated bonds; these two linear units contain Mn(1), Mn(2), Mn(3) and Mn(1$'$), Mn(2$'$), Mn(3$'$). The linear [MnO$_{4}$] is commonly encountered as a recognizable subfragment of higher nucleity Mn clusters, such as Mn$_{11}^{30}$ and Mn$_{18}^{8}$ but has never been isolated as a discrete unit in a trinuclear system.

Complex 2·3CH$_{3}$Cl$_{2}$·H$_{2}$O crystallizes in the triclinic space group P1 with the Mn$_{7}$ cation in a general position. The cation consists of six Mn atoms arranged in a ring around a central, seventh Mn atom. The Mn atoms are held together by three $\mu_{3}$-OH$^-$ ions and nine bridging and chelating hmp$^{-}$ ligands. Peripheral ligation is completed by three terminal chloride ions. Six of the hmp$^{-}$ ligands contain $\mu_{2}$-O atoms, and three contain $\mu_{3}$-O atoms, the latter comprising atoms O(1), O(3), and O(5), which together with the $\mu_{3}$-OH$^-$ ions, O(2), O(4), and O(6), hold in place the central Mn(1) atom. All the Mn atoms are six-coordinate and possess near-octahedral geometry. On the basis of bond valence sum calculations and the identification of the Jahn–Teller distortions expected for Mn$^{III}$ ions, the Mn$_{7}$ cation was determined to be mixed-valent 4Mn$^{IV}$, 3Mn$^{III}$. Atoms Mn(1), Mn(2), Mn(4), and Mn(6) are the Mn$^{IV}$ ions, and Mn(3), Mn(5), and Mn(7) are the Mn$^{III}$ ions. In addition, atoms O(2), O(4), and O(6) were identified as part of the O$^-$ ions by bond valence sum calculations and the presence of hydrogen-bonding contacts to the chloride anion Cl(4), which is closely associated with the complex (Figure 3, bottom). The distances from Cl(4) to these hydroxide O atoms O(2), O(4), and O(6) are 3.176(3), 3.160(3), and 3.214(3) Å, respectively, which are values typical of O–H⋯Cl hydrogen bonds.

cation has virtual $C_3$ symmetry. The Jahn–Teller elongation axes at the Mn$^{III}$ ions are N(2)–Mn(3)–O(3), N(6)–Mn(5)–O(5), and N(9)–Mn(7)–O(1), each involving one of the $\mu_1$–O atoms of the hmp$^+$ ligands. The core of complex 2 is also relatively planar, as emphasized in Figure 3, and in analogy with 1 can be described as consisting of six Mn$\text{O}_4$ partial cubane units, each doubly face-sharing and all vortex-sharing at the central Mn ion. In addition, complex 2 has an alternating O, Mn, O layered structure (Figure 3, bottom), similar to that in complex 1.

**Magnetic Susceptibility Studies.** Solid-state variable-temperature magnetic susceptibility measurements were performed on a vacuum-dried sample of complex 1•$\frac{1}{2}$py, suspended in eicosane to prevent torquing. The dc magnetic...
susceptibility ($\chi_M$) data were collected in the 5.0–300 K range in a 0.5 T magnetic field (Figure 4). The $\chi_M T$ value gradually decreases from 17.87 cm$^3$ mol$^{-1}$ K at 300 K to 1.14 cm$^3$ mol$^{-1}$ K at 5.0 K. The value of $\chi_M T$ at 300 K is much lower than that expected for a cluster of 10 noninteracting Mn$^{III}$ ions (30.00 cm$^3$ mol$^{-1}$ K for $g = 2$), suggesting the presence of intramolecular antiferromagnetic exchange interactions between the constituent Mn$^{III}$ ions. Because of the topological complexity of the molecule, it is not possible to determine the individual pairwise Mn$_2$ exchange interactions using the Kambe method,$^{31}$ but the experimental data strongly suggest that the cation has a ground-state spin value of $S = 0$.

Similar solid-state variable-temperature magnetic susceptibility measurements were performed on a vacuum-dried sample of complex 2, suspended in eicosane to prevent torquing. The dc magnetic susceptibility ($\chi_M$) data were collected in the 5.0–300 K range in a 0.5 T magnetic field (Figure 5). The $\chi_M T$ value at 300 K of 26.8 cm$^3$ mol$^{-1}$ K is essentially the value expected if the constituent Mn$^{II}$Mn$^{III}$ ions were noninteracting (26.5 cm$^3$ mol$^{-1}$ K for $g = 2$), and it increases with decreasing temperature to a maximum of 37.9 cm$^3$ mol$^{-1}$ K at ~10 K, before decreasing at lower temperatures. The maximum indicates a relatively large spin ground state ($S$), and the low-temperature decrease is assigned to a combination of zero-field splitting (ZFS) and intermolecular antiferromagnetic exchange interactions or both. Although complex 2 is smaller than 1, it is still not possible to apply the Kambe method.

To determine the spin of the ground state, magnetization ($M$) measurements were performed in the 1.80–4.00 K temperature range and the 0.5–3.0 T dc magnetic field range. The data are plotted as reduced magnetization ($M/N\mu_B$) versus $H/T$ in Figure 6, where $N$ is Avogadro’s number, $\mu_B$ is the Bohr magneton, and $H$ is the applied magnetic field. For a system occupying only the ground state and experiencing no ZFS, the various isofield lines would be superimposed and $M/(N\mu_B)$ would saturate at a value of $gS$. The nonsuperposition of the isofield lines in Figure 6 is indicative of the presence of significant zero-field splitting. The data were fit using the method described elsewhere$^{14,32}$ that involves diagonalization of the spin Hamiltonian matrix, assuming only the ground state is occupied at these temperatures and including axial ZFS ($D S^2$), Zeeman interactions, and a full powder average of the magnetization. The best and equally good fits to the data are obtained with $S = 10$, $g = 2.13$, $D = -0.14$ cm$^{-1}$ ($-0.20$ K) and $S = 11$, $g = 1.94$, $D = -0.11$ cm$^{-1}$ ($-0.16$ K), with the latter fit being slightly preferred because of its reasonable $g$ value. The quality of the fit is reasonable but not as good as normal, and we attribute this

to the population of low-lying excited states, even at these low temperatures. This is a frequently encountered situation in molecules containing MnII ions, because exchange interactions involving them are typically very weak (<1 cm⁻¹) and the resulting energy separations are consequently very small. In fact, given the large content of MnII in complex 2, it is thus very likely that the ground state is near in energy to many other spin states not very far away in energy. We conclude that the Mn⁷ cation has an approximately S = 10 or 11 ground state but are unable with present data to be any more definitive. Nor can we accurately determine the value of D from these data, given that the indicated values above are only rough estimates because of the less than perfect fits and the fact that axial symmetry is assumed (i.e., the rhombic ZFS parameter E is taken as zero). Similar conclusions regarding the spin ground state were made for NEt₄[Mn⁷(OH)₃Cl₃(hmp)₉(Cl)(MnCl₄)].⁲⁰ [Mn⁷(teaH)₃(tea)₃]- (ClO₄)₂, with a similar core to complex 2 and with the same Mn⁷⁺Mn⁷⁺ formulation, was concluded from detailed studies to have an S = 11 ground state, lending support to our present conclusions about the ground-state spin of 2.²²

Hysteresis Measurements below 1.8 K. Complex 2 possesses an S = 10 or 11 ground state, and it was thus considered a possibility that it might be a single-molecule magnet (SMM). If this were the case, then it should exhibit slow relaxation (reorientation) of its magnetization vector. One way of detecting this is the appearance of an imaginary (out-of-phase) signal (Z″) in the alternating current (ac) magnetic susceptibility. No such signal was observed down to 1.8 K, the operating limit of our SQUID magnetometer, when 1 was subjected to an ac field of 3.5 G oscillating at frequencies up to 1500 Hz. It was still possible that slow magnetization relaxation might be seen at temperatures below 1.8 K, and this was explored with single-crystal studies down to 0.04 K using a micro-SQUID instrument.¹¹ Figure 7 shows the plots observed in a magnetization versus dc field scan at 0.04 and 0.3 K. A very slight hysteresis behavior was seen, but the coercivity (width) of the loop was independent of the scan rate at 0.04 K and was also essentially so at 0.3 K. This is not the behavior expected from SMMs, which display a marked increase in coercivity with increasing scan rate. Similarly, at a fixed scan rate there was essentially no temperature dependence of the coercivity in a magnetization versus dc field plot (Figure 8). (Note that the field axes in Figures 7 and 8 have been greatly expanded to show what little scan rate or temperature dependence is present.) These results strongly suggest that complex 2 is not a SMM and that the small hysteresis observed at very low temperature is due to intermolecular exchange interactions and long range ordering. The intermolecular interactions need only be very

weak and likely have their origin from both dipolar and exchange contributions.

The absence of a significant barrier to magnetization relaxation for a species with such a large ground-state $S$ value suggests that the ZFS parameter $D$ is very small. The upper limit of the energy barrier to relaxation is $S^2 |D|$, and it is likely, therefore, that $|D| < 0.1$ cm$^{-1}$ and perhaps significantly less. In fact, the previously reported complex [Mn$_7$-(teaH)$_3$(tea)$_3$]$^{2+}$ mentioned above, which has a similar Mn$_7$ core to that in 2, has been shown by EPR measurements to have $D = -0.08$ cm$^{-1}$ and a rhombic zero-field splitting parameter, $E = -2.1 \times 10^{-4}$ cm$^{-1}$. Such a correspondingly small $D$ value is likely also for 2 and is actually consistent with the structure of this cation. The main sources of the molecular anisotropy are the three JT distorted Mn$^{III}$ ions. The projections of the these single-ion anisotropies onto the molecular anisotropy axis will determine the value of the molecular $D$ parameter. As described above, the three Mn$^{III}$ JT elongation axes are the N(2)$\cdots$Mn(3)$\cdots$O(3), N(6)$\cdots$Mn(5)$\cdots$O(5), and N(9)$\cdots$Mn(7)$\cdots$O(1) axes (Figure 2), which are disposed in a propeller-like fashion and lie almost in the Mn$_7$ plane. Thus, the projections of these onto the molecular easy axis ($z$ axis) will give a very small net molecular axial anisotropy, $D$. In any case, as already mentioned, the value $S^2 |D|$ merely represents the upper limit ($U$) to the energy barrier, with the true (or effective) barrier ($U_{\text{eff}}$) to magnetization relaxation being significantly less because of quantum tunneling of the magnetization through the barrier via higher energy $M_S$ levels of the ground $S$ state.

### Conclusions

Decanuclear complex 1 has been obtained from the reaction of [Mn$_7$O(O$_2$CMe)$_6$(py)$_3$](ClO$_4$) with hmpH and possesses an $S = 0$ ground state. In contrast, the comproportionation reaction between MnCl$_2$$\cdot$4H$_2$O and NBu$^n$_4MnO$_4$ in the presence of hmpH yields heptanuclear complex 2, which has an $S = 10$ or 11 ground state. The dramatic difference in ground-state spin values for complexes with not too dissimilar nuclearities and ligation emphasizes the difficulty in trying to deliberately synthesize complexes with large spin values. In addition, the described results also emphasize that in the search for new SMMs, obtaining a large spin value is not enough: $S \geq 10$ is one of the largest spin values ever obtained for a molecular cluster, but in the absence also of a significant anisotropy, as reflected in the ZFS parameter $D$, the magnetization relaxation is fast, and the molecule is not an SMM. Nevertheless, other areas of Mn cluster chemistry continue to provide new examples of SMMs, and the number of known examples continues to grow.
