The reaction of 2-(hydroxyethyl)pyridine (hepH) with a 2:1 molar mixture of [Mn$_3$O(O$_2$CMe)$_6$(py)$_3$]ClO$_4$ and [Mn$_3$O(O$_2$CMe)$_6$(py)$_3$] in MeCN afforded the new mixed-valent (16Mn$^{III}$, 2Mn$^{II}$), octadecanuclear complex

$$\text{[Mn}_{18}\text{O}_{14}(\text{O}_{2}\text{CMe})_{18}(\text{hep})_{4}(\text{hepH})_{2}(\text{H}_{2}\text{O})_{2}]\text{(ClO}_{4})_{2}$$

in 20% yield. Complex 1 crystallizes in the triclinic space group $P\overline{1}$. Direct current magnetic susceptibility studies in a 1.0 T field in the 5.0 − 300 K range, and variable-temperature variable-field dc magnetization studies in the 2.0 − 4.0 K and 2.0 − 5.0 T ranges were obtained on polycrystalline samples. Fitting of magnetization data established that complex 1 possesses a ground-state spin of $S = 13$ and $D = -0.18$ K. This was confirmed by the value of the in-phase ac magnetic susceptibility signal. Below 3 K, the complex exhibits a frequency-dependent drop in the in-phase signal, and a concomitant increase in the out-of-phase signal, consistent with slow magnetization relaxation on the ac time scale. This suggests the complex is a single-molecule magnet (SMM), and this was confirmed by hysteresis loops below 1 K in magnetization versus dc field sweeps on a single crystal. Alternating current and direct current magnetization data were combined to yield an Arrhenius plot from which was obtained the effective barrier ($U_{\text{eff}}$) for magnetization reversal of 21.3 K. Below 0.2 K, the relaxation becomes temperature-independent, consistent with relaxation only by quantum tunneling of the magnetization (QTM) through the anisotropy barrier via the lowest-energy $M_S = \pm 13$ levels of the $S = 13$ spin manifold. Complex 1 is thus the SMM with the largest ground-state spin to display QTM.

**Introduction**

There are many specialized applications of magnets that require monodisperse, nanoscale magnetic particles, and the discovery that individual molecules can function as nanoscale magnets was thus a significant development for the field of magnetism and magnetic materials. Such molecules have since been named single-molecule magnets (SMMs). SMMs function as single domain magnetic particles that, below their blocking temperature ($T_B$), exhibit the classical property of a magnet, namely magnetization hysteresis. In addition, SMMs straddle the classical/quantum interface in also displaying quantum tunneling of magnetization (QTM) and quantum phase interference. An SMM derives its unusual properties from a combination of large spin ($S$) and large, easy axis-type anisotropy (negative axial zero-field splitting parameter $D$). These result in a significant barrier to thermally...
activated magnetization relaxation, with upper limits given by \( S^2 |D| \) or \( (S^2 - 1/4)|D| \) for integer and half-integer spin, respectively. The first SMM was \([\text{Mn}_{12}\text{O}_{12}\text{CMe}_6\text{H}(\text{H}_2\text{O})_4]\), with \( S = 10 \) and \( D = -0.50 \text{ cm}^{-1} = -0.72 \text{ K} \). Since then, other oxidation levels of the \([\text{Mn}_{12}]\) family, 6,7 have also been prepared with various \( S \) values, both integer and half-integer.8,11

Recently, the first exchange-coupled dimer of SMMs has demonstrated the feasibility of fine-tuning the quantum properties of these nanoscale magnetic materials.12 Most known SMMs contain Mn(III). This is due to the combination of a large number of unpaired electrons on each high-spin, near-octahedral Mn(III) ion and the Jahn–Teller (JT) distortion that accompanies it, usually in the form of an axial elongation.13 The JT distortion results in a significant magnetosanisotropy, as gauged by the zero-field splitting (ZFS) parameter \( D \), which is always negative for axially elongated Mn, stabilizing the largest value of \( M_S \) and giving rise to a uniaxial barrier for the relaxation of the magnetization, i.e., Ising or easy-axis anisotropy.

The nanoscale dimensions of SMMs place them at the quantum/classical interface, and the phenomenon of quantum tunneling of the magnetization (QTM) can be observed as steps in the hysteresis loops. Additionally, QTM within the ground-state (i.e., lowest energy) \( M_S \) levels can be observed as temperature-independent relaxation at low enough temperatures. This has been observed for several SMMs.5,6,12,14,15

**Experimental Section**

All manipulations were performed under aerobic conditions, using materials as received. \([\text{Mn}_9\text{O}_6\text{CMe}_3\text{py}(\text{py})_3]\text{ClO}_4 \text{and } [\text{Mn}_9\text{O}_6\text{CMe}_3(\text{py})_3] \) were prepared as previously described.18

\([\text{Mn}_{18}\text{O}_{14}\text{CMe}_18\text{ClO}_4\text{ClO}_4\text{py}_2\text{H}_2\text{O}_2] \) (I). To a solution of \([\text{Mn}_9\text{O}_6\text{CMe}_3(\text{py})_3]\text{ClO}_4 \) (0.50 g, 0.57 mmol) and \([\text{Mn}_9\text{O}_6\text{CMe}_3(\text{py})_3]\text{py}_3 (0.24 g, 0.29 mmol) in MeCN (40 mL) was added heph (0.16 g, 1.30 mmol). The resulting solution was stirred overnight, filtered through Celite, and layered with two volumes of Et_2O. After several weeks, the crystals that had formed were isolated by filtration, washed with Et_2O and dried in vacuo; yield 20%. A sample for crystallography was kept in contact with the mother liquor to prevent interstitial solvent loss. The vacuum-dried sample analyzed as unsolvated. Anal. Calcd (Found) for \([\text{Mn}_{18}\text{O}_{14}\text{CMe}_18\text{ClO}_4\text{ClO}_4\text{py}_2\text{H}_2\text{O}_2] \): 15.87 (15.87), 11.32 (11.32), 15.87 (15.87), 15.87 (15.87), 15.87 (15.87). Selected IR data (KBr disk, cm\(^{-1}\)): 1577 (vs), 1485 (m), 1442 (s), 1398 (s), 1334 (m), 1248 (m) and 1107 (s), 1089 (s), 1070 (s), 1032 (s), 939 (s), 873 (w), 769 (m), 711 (m), 663 (s), 625 (s), 588 (s).

**Physical Methods.** Infrared spectra (KBr disk) were recorded on a Nicolet NEXUS 670 spectrometer. Elemental analyses were performed by Atlantic Microlab, Inc., Norcross, GA, or at the in-house facility at the Department of Chemistry, University of Florida. Variable-temperature magnetic susceptibility data were collected on powdered microcrystalline samples (restrained in eicosane to prevent torquing) with a Quantum Design MPMS-XL SQUID magnetometer equipped with a 5 T magnet. Pascal’s constants were used to estimate the diamagnetic correction, which was subtracted from the experimental susceptibility to give the molar magnetic susceptibility (\(\chi_m\)). Magnetization versus field hysteresis and dc decay measurements at temperatures below 1.8 K were performed on single-crystals using a micro-SQUID instrument.19

---

X-ray Crystallography and Structure Solution. Data were collected on a Bruker platform goniometer equipped with a SMART APEX CCD area detector and a graphite monochromator utilizing Mo Kα radiation (λ = 0.71073 Å). A suitable crystal of 1·6MeCN was mounted on a glass fiber using silicone grease and transferred to the diffractometer where it was cooled to 223 K for characterization and data collection. The intensity data were collected using the Φ- and ω-scan methods, with a scan step ΔΦ = Δω = 0.03°. The first 50 frames were remeasured at the end of data collection to monitor instrument and crystal stability. The data were corrected for Lorentz and polarization effects using the Bruker SAINT software, and an absorption correction was performed using the DIFABS program supplied by Bruker AXS. The structure was solved by direct methods and standard Fourier techniques, and was refined on F² using full-matrix least-squares method (SHELXTL). All non-H atoms were refined anisotropically; H-atoms were placed in calculated positions and refined with the use of a riding model. Unit cell parameters and data collection and refinement details are listed in Table 1.

Results and Discussion

Synthesis. The trinuclear Mn complex [Mn₃O(O₂CMe)₆(py)₃](ClO₄)₂ has previously been found to be useful starting material for the synthesis of new Mn–carboxylate complexes. Reactions of this complex with appropriate chelating ligands have afforded a variety of new clusters with a variety of nuclearities. Of relevance to the present work is the previously studied reaction of [Mn₃O(O₂CMe)₆(py)₃](ClO₄)₂ with 3 equiv of hydroxymethylpyridine (hmpH) in CH₂Cl₂, which was found to give the decanuclear Mn(III) complex [Mn₁₈O₆(OH)₉(O₂CMe)₆(hmpH)]₂(ClO₄)₄. The organic compounds hmpH and hepH are structurally very similar (Chart 1), only differing in an extra CH₂ group in the alcohol arm. In contrast with the results obtained with hmpH, the reaction of [Mn₃O(O₂CMe)₆(py)₃](ClO₄)₂ in MeCN with 3 equiv of hepH afforded the new mixed valent [Mn(II)₃Mn(III)₁₈] complex [Mn₁₈O₆(O₂CMe)₆(hepH)₆(hepH)]₂-

(H₂O)₂][ClO₄]₂ (1). However, the yield of complex 1 was <5% and the preparation difficult to reproduce; thus, a better route to this compound was sought and subsequently developed.

Since complex 1 contains some Mn(II), indicating that the formation of this product requires some disproportionation or reduction of Mn(III) in the starting material to occur, we explored whether deliberately adding a Mn(II) source might provide a more reliable route to 1. Thus, we investigated the reactions of hepH with a mixture of [Mn₃O(O₂CMe)₆(py)₃](ClO₄)₂ and its mixed-valence Mn(II), Mn(III) version, [Mn₃O(O₂CMe)(py)]₃. Indeed, the reaction of an MeCN solution of [Mn₃O(O₂CMe)(py)]₃ with [Mn₃O(O₂CMe)(py)]₃ in a 2:1 ratio with 1.5–3 equiv of hepH afforded 1 in a reproducible yield of 20%. This ratio of Mn₃ reagents is that calculated to give a 16Mn(III)/2Mn(II) oxidation state ratio. The overall transformation is summarized in eq 1.

\[
4[Mn₃O(O₂CMe)₆(py)₃] + 2[Mn₃O(O₂CMe)₆(py)₃] + 6hepH + 10H₂O \rightarrow \\
[Mn₁₈O₁₄(O₂CMe)₁₈(hepH)₆(hepH)₂(H₂O)₂]^{2+} + 18MeCO₂H + 2H^+ + 18py \quad (1)
\]

The 2:1 reaction ratio of Mn₃ reagents does not require any redox processes. However, subsequent reactions exploring the effect of varying the ratio from 2:1 to 1:2 always afforded the same complex 1 as the only isolable product, although the 2:1 ratio does give the highest yield.

Description of Structure. [Mn₁₈O₁₄(O₂CMe)₁₈(hepH)₆(hepH)₂(H₂O)₂](ClO₄)₂·6MeCN (1·6MeCN) crystallizes in the triclinic space group P1. Selected bond distances and angles are listed in Table 2, and an ORTEP representation and stereoview of the cation are presented in Figure 1. The structure consists of one [Mn₁₈]2⁺ cation and two perchlorate anions per unit cell, with the former lying on a crystallographic inversion center. The cation of 1 can be described as disc-shaped with 10 of the metals in a nearly planar arrangement and Mn(4), Mn(7), Mn(8), and Mn(9) and their symmetry related Mn(4)', Mn(7)', Mn(8)', and Mn(9)' lying above and below the plane, as shown in Figure 2. It consists of a [Mn₁₈(μ₄-O)₁₆(μ₃-O)₂]₅⁺ core (Figure 2), with the four μ₄-O atoms (O(22), O(23), O(22)', and O(23)') and 10 of the μ₃-O atoms (O(19), O(20), O(21), O(24), O(25), O(19)', O(20)', O(21)', O(24)', and O(25)') atoms being O²⁻ ions. The remaining two μ₂-O atoms (O(10) and O(10)') are from μ₂-MeCO₂⁻ groups, an extremely rare binding mode for this ligand in molecular clusters. Of the eight μ₂-O atoms, six are part of hepH ligands (O(26), O(27), O(28), O(26)', O(27)', and O(28)'), and the other two (O(4) and O(4)') are from bridging syn,syn,anti-MeCO₂⁻ groups. The core can be described as a central [Mn₉O₆] unit (containing a linear Mn₉ chain) linked by its μ₃-O²⁻ ions to two [Mn₆O₆] units, one on each side. Each of the latter comprises a face-sharing set of one [Mn₆O₆] cubane and two [Mn₆O₆] partial cubanes. All of the Mn centers are hexacoordinated. Peripheral ligation is provided by acetate groups and the hepH/ hepH ligands.

Close examination of the metric parameters (Table 2) and bond valence sum calculations\(^{22,23}\) for the Mn atoms (Table 3) reveals a mixed- and trapped-valence oxidation state description of 16 Mn(III) and 2 Mn(II) centers. The two Mn(II) ions are Mn(9) and Mn(9). Bond valence sum calculations were also performed on the oxygen atoms\(^{22,24}\) of the cluster to identify their protonation level (Table 4), and this revealed two terminal water molecules, O(29) and O(29), and two protonated hepH ligands, O(27) and O(27).
These determined protonation levels and metal oxidation states are consistent with an overall \([\text{Mn}_{18}]^{2+}\) charge for the cation of 1, as revealed by the two \(\text{ClO}_4^-\) anions in the crystal structure.

All the Mn(III) atoms show the expected Jahn--Teller (JT) distortion of high-spin Mn(III) in near-octahedral geometry, and this takes the form of an axial elongation in every case. Ten of the metal centers (Mn(1), Mn(2), Mn(3), Mn(5), Mn(6), and their symmetry partners) are coplanar, with their JT elongation axes aligned approximately parallel to each other and perpendicular to the plane, as shown in Figure 2 (bottom). The remaining six Mn(III) atoms (Mn(4), Mn(7), Mn(8), and their symmetry partners) lie above and below this plane: the JT axes on Mn(7), Mn(8), Mn(7)', and Mn(8)' lie approximately parallel to the plane of the molecule, and thus are essentially perpendicular to the majority JT orientations, whereas those on Mn(4) and Mn(4)' are at an intermediate orientation. This will be of relevance to the magnetic properties to be discussed below.

The \(\text{Mn}_{18}\) cations in the triclinic \(\text{P}1\) lattice are stacked in columns, and all of the molecules are oriented in the same way with respect to the cell axes. Between molecules in the same column, there is no evidence of hydrogen-bonding or any other close contact. Between columns there are narrow channels filled with MeCN solvent molecules, which are disordered due to insignificant interaction with any of the anions or cations around them. The only significant intermolecular interaction is \(\pi\)-stacking of the hep⁺ pyridine rings bound to Mn(8) atoms in \([\text{Mn}_{18}]^{2+}\) cations in different columns along the \(c\)-direction of the cell; this is shown in Figure 3 as dashed lines. The aromatic rings are perfectly parallel and separated by 3.7 Å. Thus, apart from this \(\pi\)-stacking, each cation is fairly isolated from its neighbors.

in the crystal. This fact will also be important when interpreting the magnetic properties of the complexes.

**Direct Current Magnetic Susceptibility Studies.** Direct current magnetic susceptibility studies were performed on a microcrystalline sample of complex 1 in the 5.0–300 K range and a 1 T applied field. Figure 4 shows the molar magnetic susceptibility (χₘ) of complex 1 as a χₘT versus T plot. The χₘT has a value of 38.9 cm³ K mol⁻¹ at 300 K, gradually decreasing with decreasing temperature to a plateau value of 26.4 cm³ K mol⁻¹ between 40 and 15 K, and then sharply decreasing to 9.8 cm³ K mol⁻¹ at 5.0 K. The χₘT value at 300 K is significantly smaller than the spin-only value of 56.75 cm³ K mol⁻¹ expected for 18 noninteracting Mn centers with the oxidation states found in complex 1.

These dc data are thus consistent with predominantly antiferromagnetic interactions between the metal centers, but with a relatively large ground-state spin. To determine the exact values of the many pairwise Mn₂ exchange parameters and to find all of the possible spin states and their energies, the spin Hamiltonian for this complex would have to be diagonalized. However, such a matrix-diagonalization approach would involve a matrix of dimensions of 549 × 10¹⁰ by 549 × 10¹⁰, and such a calculation is essentially unfeasible with current computing capabilities. It is also not possible, due to the complexity of the system, to apply the equivalent operator approach, based on the Kambe vector coupling method, as is usually possible with smaller systems. Thus, we concentrated instead on identifying only the ground-state spin (S) of the complex, which would in any case dominate the very low-temperature magnetic studies to be discussed later.

Variable-temperature, variable-field dc magnetization (M) data were collected in the 2.0–4.0 K range at applied dc fields (H) ranging from 2.0 to 5.0 T. The obtained data are plotted as reduced magnetization (M/N_μ) versus H/T in Figure 5. The data were fit by diagonalization of the spin Hamiltonian matrix using a full powder-average method that assumes only the ground state is populated and incorporates axial ZFS (Dₛ²) and Zeeman effects. The method is described in detail elsewhere. The best fit gave a ground-state spin of S = 13, D = −0.13 cm⁻¹ (−0.18 K) and g = 1.86, and is shown in Figure 5 as the solid lines. If data collected at lower fields were included, a good fit could not be obtained. This is indicative of the presence of low-lying excited states, as expected (i) for such a high nuclearity cluster, which will consequently have a high density of spin states, and (ii) for a molecule containing Mn(II) ion, since these display weak exchange interactions, and consequently small energy separations between spin states.

However, what is not clear from these data and fit by themselves is whether the S = 13 state is the ground state, or whether it is one of the lowest-lying excited states above

---

a ground state with an $S < 13$ spin. In the latter case, the $M_z$ component of the $S = 13$ excited state would cross below those of the ground state in large fields, and the magnetization fits would thus appear to indicate an $S = 13$ ground state, which would not be the true case. Such an incorrect determination of the ground state spin is always a danger when low-lying excited states are present and a large dc field is employed, and we have elsewhere described how we avoid this by using only weak dc fields to avoid level crossings in cases where the low-lying excited states have a bigger spin than the ground state.\textsuperscript{9,10} In the present case, however, the in-phase ac susceptibility studies (which will be described below), carried out in an oscillating ac field of only 3.5 G, serve to indicate that the $S = 13$ state really is the ground state of the molecule, with the low-lying excited states having smaller $S$. Thus, the use of large dc fields provides data and subsequent fit values of $S$ and $D$ that are not an artifact of level crossing, and thus reliable.

The obtained $D$ value is relatively small compared with other Mn complexes such as $[\text{Mn}_{12}\text{O}_{12}(\text{O}_2\text{CMe})_{16}(\text{H}_2\text{O})_4]$ ($D = -0.5\ \text{cm}^{-1} = -0.71\ \text{K}$),\textsuperscript{1–3} even though the molecule possesses 16 Mn(III) instead of only eight of them as in $[\text{Mn}_{12}\text{O}_{12}(\text{O}_2\text{CMe})_{16}(\text{H}_2\text{O})_4]$. This can be rationalized as reflecting the difference in the relative orientations of the Mn(III) JT axes in the two types of molecule. The JT distorted Mn(III) ions are the main source of the molecular anisotropy (i.e., the magnitude of the molecular zero-field splitting parameter, $D$), which is a projection of the Mn(III) single-ion anisotropies onto the molecular anisotropy ($z$) axis. In the Mn$_{12}$ complex, the eight Mn(III) JT axes are very roughly all parallel leading to a much larger $|D|$ value than for the cation of I, which has 10 JT axes roughly parallel, but with four of the remaining six perpendicular to them and the other two in an intermediate orientation. As a result, it is qualitatively reasonable that the $D$ value for I should be smaller (less negative) than that for the Mn$_{12}$ clusters.

Even though higher spin values are known, the $S = 13$ ground-state spin of complex I is nevertheless an unusually large spin for a molecular species. The currently largest spin for any molecular species is the $S = 5/2$ of a Mn$_{25}$ complex,\textsuperscript{28} and a Mo$_9$Mn$_9$ complex.\textsuperscript{29} As mentioned in the Introduction, the upper limit to the barrier to magnetization reversal is given by $U = S^2|D|$ for an integer spin system, although the actual or effective barrier ($U_{\text{eff}}$) is significantly less due to quantum tunneling of the magnetization (QTM) through the barrier via higher energy $M_3$ levels. The large $S = 13$ spin is beneficial for providing a large barrier, but the small $D$ value counterbalances this, and the calculated $U$ value is consequently only $22.0\ \text{cm}^{-1} (=31.6\ \text{K})$. In contrast, a $D$ value of $-0.5\ \text{cm}^{-1}$, as for the Mn$_{12}$ complex, would have given a $U$ of $84.5\ \text{cm}^{-1}$ for $S = 13$. Nevertheless, a value of $U = 22.0\ \text{cm}^{-1}$ is sufficiently large to suggest that, at a low enough temperature, complex I might function as an SMM.

\textbf{Alternating Current Magnetic Susceptibility Studies.}

In an ac susceptibility experiment, a weak field (typically $1–5\ \text{G}$) oscillating at a particular frequency ($\nu$) is applied to a sample to probe the dynamics of the magnetization (magnetic moment) relaxation. Alternating current susceptibility data were collected on a microcrystalline sample of I in the $0.04–4.0\ \text{K}$ range at nine frequencies from 1.1 to 996 Hz. Both the resulting in-phase ($\chi_{\prime}$) and the out-of-phase ($\chi_{\prime\prime}$) ac susceptibility data are shown in Figure 6. If the magnetization vector can relax fast enough to keep up with the oscillating field, then there is no out-of-phase susceptibility signal ($\chi_{\prime\prime}$), and the in-phase susceptibility ($\chi_{\prime}$) is equal to the dc susceptibility. However, if the barrier to magnetization relaxation is significant compared to thermal energy ($kT$), then there is a nonzero $\chi_{\prime\prime}$ signal and the in-phase signal decreases. In addition, the $\chi_{M}$ signal will be frequency-dependent. As can be seen in Figure 6, a frequency-dependent $\chi_{\prime\prime}$ signal begins to appear at below $3\ \text{K}$, concomitant with a frequency-dependent decrease in the $\chi_{M}$ signal. Such frequency-dependent ac signals are a characteristic signature of the superparamagnet-like slow relaxation of an SMM, although they do not by themselves prove the presence of an SMM.

The $\chi_{M}$ data also provide crucial support for the conclusion from the dc magnetization fits described earlier that complex I possesses an $S = 13$ ground state. As can be seen in Figure 5, the $\chi_{M}/T$ value above $3\ \text{K}$ is increasing with decreasing temperature. A well isolated ground state (vs $kT$) would be expected to be essentially 100% populated at these temperatures, and thus, the $\chi_{M}/T$ value would be

![Figure 6](image.png)

\textbf{Figure 6.} Alternating magnetic susceptibility plot for I at 44 (■), 246 (△), and 996 (▲) Hz ac frequencies.

We thus decided to investigate the magnetization dynamics of this complex using ac magnetic susceptibility studies.

\textbf{References.}

Single-Molecule Magnets

expected to be essentially temperature-independent. A sloping $\chi_M(T)$ versus $T$ plot is indicative of low-lying excited states whose changing population with temperature affects the observed $\chi_M(T)$. In several cases, we have observed that the $\chi_M(T)$ value decreases significantly with decreasing $T$, and this is consistent with low-lying excited states with $S$ values greater than that of the ground state. As they become depopulated with decreasing $T$, the $\chi_M(T)$ value approaches that to the ground state. Extrapolation of the $\chi_M(T)$ plot to 0 K gives a value of $\sim 79 \text{ cm}^{-1} \text{ K} \text{ mol}^{-1}$, which is consistent with $S = 13$ and $g = 1.86$, in satisfying agreement with the fit of the magnetization data. The in-phase value of $\sim 79 \text{ cm}^{-1} \text{ K} \text{ mol}^{-1}$ is also consistent with $S = 14$ and $g = 1.73$, and $S = 12$ and $g = 2.01$, which are less favored because of the $g$ values but nevertheless reasonable, and so the safest conclusion from the in-phase ac data alone is that complex 1 has an $S = 13 \pm 1$ ground state. However, even this is enough to allow us to rationalize the described problems with the dc magnetization fits at lower fields. At lower fields, some of the excited states will be populated even at the lowest temperatures, and this will give a poor fit since the fitting model assumes only the ground state is populated. At higher fields, however, the energy gap between the lowest-lying $M_S$ components of the ground state and $M_S$ levels of excited states will be greatly increased, and essentially only the former will be populated, allowing a good fit and reliable determination of the ground-state $S$. We thus conclude that the fit of Figure 5 is indeed reflecting the ground state, that the obtained fit parameters are reliable, and that complex 1 thus possesses an $S = 13$ ground state.

**Magnetization Hysteresis Studies.** With the combined dc and ac susceptibility studies revealing that complex 1 has an $S = 13$ ground state and $D = -0.13 \text{ cm}^{-1}$, and exhibits out-of-phase ac susceptibility signals suggestive of a single-molecule magnet, we sought to confirm whether 1 is an SMM by determining whether it exhibits hysteresis in magnetization ($M$) versus dc field sweeps, the diagnostic property of a magnetic material.

Magnetization versus applied dc field data were collected on single crystals (that had been kept in contact with mother liquor) using a micro-SQUID instrument. The magnetization responses with the field approximately along the easy axis (z-axis) of the molecule are shown in Figure 7, where both the temperature dependence at a constant field sweep rate of 0.07 T/s (Figure 7, top) and the field sweep rate dependence at a constant temperature of 0.04 K (Figure 7, bottom) are shown. Hysteresis loops were indeed observed below $\sim 1 \text{ K}$, whose coercivities increase with decreasing temperature and increasing sweep rate, as expected for the superparamagnet-like properties of a SMM below its blocking temperature ($T_B$). The data thus indicate complex 1 to be a new addition to the family of SMMs. The blocking temperature ($T_B$) is $\sim 1.0 \text{ K}$, above which there is no hysteresis, i.e., the spin relaxes faster to equilibrium than the time scale of the hysteresis loop measurement.

For several other SMMs studied to date, the hysteresis loops have not been smooth but have instead displayed steplike features at periodic field values.30 These steps correspond to positions of increased magnetization relaxation rates and are due to quantum tunneling of the magnetization (QTM) through the anisotropy energy barrier.19 The loops in Figure 7 do not show such periodic steps, although there does appear to be one barely visible at zero field. It was suspected that complex 1-6MeCN does in fact exhibit QTM but that the steps have been broadened to the point that they have been smeared out and thus not visible. Similar behavior has been observed for certain other SMMs such as Mn$_{21}^6$,9 Mn$_{30}^{10}$ and Mn$_{64}^{11}$ species, and this has been assigned to a distribution of energy relaxation barriers (i.e., a distribution in $D$ values) due to a distribution in local molecular environments. The separation between steps is directly proportional to $D$, so a distribution in $D$ would give a distribution in step positions and thus a broadening. Such a distribution is consistent with the crystallographic disorder observed in the MeCN molecules in the crystal lattice. In

![Figure 7. Magnetization ($M$) vs field ($H$) hysteresis loops for a single crystal of 1-6MeCN at (top) a constant scan rate of 0.07 T/s and the indicated temperatures, and (bottom) at 0.7 K and the indicated scan rates. The magnetization is normalized to its saturation value $M_S$.](image)

effect, the local environments around the [Mn$_{18}$]$^{2+}$ cations vary as a result of these disorders, altering the value of $D$. Disorder in the solvent molecules was also present in the Mn$_{30}$ and Mn$_{84}$ SMMs that also did not display steps in their hysteresis loops. Such observations continue to emphasize the sensitivity of SMMs to relatively small changes in the local environments of the molecules. Other sources of step broadening that probably contribute to the absence of steps in Figure 7 include intermolecular dipolar and exchange interactions, particularly given the large spin of the cation of 1 and the π-stacking interactions between cations seen in the crystal structure, and of course crystal impurity and defect sites.

Although steps are not clearly visible in the hysteresis loops, they nevertheless provide other evidence of QTM. Below 0.2 K, the loops become temperature independent, but a scan rate study shows that the loops are still time-dependent (Figure 7). This is better illustrated in Figure 8, where the coercive field (half the width of the hysteresis loop at $M/M_s = 0$) is plotted as a function of temperature for different field scan rates. Below ~0.2 K, the coercive field is temperature-independent (a plateau) at a given scan rate, but scan-rate (i.e., time)-dependent at a given $T$. This is supportive of QTM from the ground-state $M_s = -13$ of the $S = 13$ spin manifold to $M_s < 13$ levels on the other side of the potential energy double well.

An alternative way of assessing whether QTM is occurring is to identify the presence of temperature-independent relaxation. For this, we constructed an Arrhenius plot. The ac data in Figure 6 are one source of kinetic data, since at the temperature of the peak maximum of the $\chi''_M$ signal, the relaxation rate ($1/\tau$, where $\tau$ is the relaxation lifetime) is equal to the angular frequency $\omega (= 2 \pi \nu$, where $\nu$ is the ac field oscillation frequency). To supplement these data, dc magnetization decay data were collected: (i) on a polycrystalline sample using a SQUID instrument (Figure 9, top). Each of the 27 data sets was analyzed to give a relaxation time ($\tau$). The dc decay and ac $\chi_M$ data were combined and used to construct an Arrhenius plot of $\ln \tau$ versus $1/T$ (Figure 9, bottom), based on the Arrhenius relationship of eq 2, where $1/\tau_0$ is the pre-exponential factor (attempt frequency), $U_{\text{eff}}$ is the mean effective barrier to relaxation, and $k$ is the Boltzmann constant.

$$\frac{1}{\tau} = \frac{1}{\tau_0} \exp\left(-\frac{U_{\text{eff}}}{kT}\right)$$

The fit of the thermally activated region above ~0.5 K (shown as the solid line in Figure 9, bottom) gave $U_{\text{eff}} = 14.8 \text{ cm}^{-1} = 21.3 \text{ K}$, which is less than the value of $U = S(S+1)D = 22.0 \text{ cm}^{-1} = 31.6 \text{ K}$ determined from the magnetization fits. This is as expected for QTM between higher energy $M_s$ levels of the $S = 13$ manifold; i.e., the system does not have to get to the top of the barrier (i.e., the $M_s = 0$ level), but instead can tunnel through the barrier from some lower $M_s$ level. The presence of QTM is further supported by the temperature-independence of the relaxation rate below ~0.25 K, at ~1.3 $\times$ 10$^4$ s$^{-1}$, indicative at these temperatures of QTM only between the lowest energy $M_s = \pm 13$ levels of the $S = 13$ state, i.e., ground-state tunneling. In fact, complex 1 is to date the largest spin molecule reported to display QTM.

Conclusions

The use of hepH as a chelating ligand in Mn/O chemistry has allowed access to a structurally novel [Mn₁₈]²⁺ compound, which is mixed- and trapped-valence 16Mn(III), 2Mn(II). This emphasizes the usefulness of the alkoxide functionality in promoting high-nuclearity product formation. Combined dc and ac magnetic susceptibility studies have established an unusually large ground-state spin of $S = 13$ for this compound. Together with a small but significant anisotropy, this large spin results in complex 1 being a new member of the family of SMMs, and one with a distinctly different type of structure from previous examples. The SMM property has been confirmed by hysteresis studies. The small barrier to magnetization relaxation again emphasizes the importance of both a significant $S$ and $D$ in producing SMMs with large relaxation barriers. Unfortunately, it is difficult to design high-nuclearity complexes to have one, let alone both, of these properties. With this new structural type of SMM established, however, we have since managed to make additional members of this Mn₁₈ family of SMMs at other oxidation levels, and this work will be reported in due course. Finally, as already mentioned, complex 1 is the largest spin SMM reported to date to exhibit QTM; the largest size molecules to exhibit QTM are the recently reported Mn₃₀ SMM and the giant Mn₈₄ SMM with a toroidal structure.¹¹
