Abstract

The use of 2-pyridyl oximes (L’H) in reactions with \( \text{Mn}^{\text{III}}(\text{O}_2\text{CR})_6(\text{py})_3\)(\text{ClO}_4) \) has led to complexes \( \text{Mn}^{\text{III}}(\text{O}_2\text{CR})_3\text{L}_0(\text{ClO}_4) \). Ferromagnetic exchange interactions between the three Mn\(^{\text{III}}\) ions in the complexes lead to spin ground states of \( S = 6 \). The complexes display the temperature- and scan rate-dependent hysteresis loops that are indicative of single-molecule magnetism behaviour. © 2006 Elsevier Ltd. All rights reserved.

Keywords: Ferromagnetic exchange; Manganese(III) carboxylate clusters; 2-Pyridyloximate ligands; Single-molecule magnets; Triangular oxide-centered complexes

The properties of conventional magnets are due to the collective behaviour of the unpaired electron spins of thousands or millions of individual metal ions in a particle or bulk material. Single-molecule magnets (SMMs) \([1]\), on the other hand, are transition-metal, homo- or heterometallic clusters that individually exhibit the classical properties of a magnet below a critical temperature (the blocking temperature, currently ~4 K). Their properties arise from the combination of a large spin value \( (S) \) in the ground state and significant magnetanoisotropy of the easy-axis type (manifested as a negative zero-field splitting parameter, \( D \)). Due to their small size, SMMs have also been shown to exhibit interesting phenomena of the quantum world, such as quantum tunneling of magnetization \([2]\) and quantum phase interference \([3]\).

Compared to other 3d metal ions, manganese clusters are often characterized by large spin ground states; this characteristic, in combination with the Jahn–Teller distortion of high-spin Mn\(^{\text{III}}\) ions in near-octahedral stereochemistry (the source of the single-ion anisotropy) make manganese clusters ideal candidates for SMM behaviour. Thus, it is not surprising that the majority of SMMs are Mn(III) complexes of several nuclearities and various structural types, and often mixed valent, i.e. Mn(II/III) and Mn(III/IV) \([1]\). Despite this, there is a continuing need for Mn SMMs exhibiting new structural types to improve our understanding of this exciting phenomenon. Inspection of the literature reveals that there are no oxide-centered triangular Mn SMMs. Most of these triangular complexes have the general formula \( \text{Mn}_3\text{O}(\text{O}_2\text{CR})_6\text{L}_3^{3+/4} \) (where \( L \) is a terminal ligand such as \( \text{H}_2\text{O}, \text{MeCN}, \) or pyridine) \([4]\) and are often used as starting materials in SMM synthesis...
The metal ions are antiferromagnetically coupled, and these complexes are not therefore SMMs. We are now pleased to report that the reactions of \([\text{Mn}^{III}\text{O}_2\text{CMe}]\) with \(\text{ppko}^{-}\) and \(\text{mpko}^{-}\) anions behave as \(\eta^1\eta^1\)-\(\mu\)-ligands forming five-membered chelate rings. The oxide ion lies 0.295 Å above the plane defined by the three \(\text{Mn}^{III}\) ions. The coordination geometry of the metal ions is distorted octahedral. The \(\text{O}^{2-}\) character of \(\text{O}(61)\) and the \(\text{Mn}^{III}\) oxidation states were confirmed by charge considerations, bond lengths, bond valence sum (BVS) calculations [7] and the presence of \(\text{Mn}^{III}\) Jahn–Teller elongation axes \([\text{O}(1)–\text{Mn}(1)–\text{O}(31), \text{O}(11)–\text{Mn}(2)–\text{O}(51), \text{O}(21)–\text{Mn}(3)–\text{O}(42)]\). The trinuclear cations of complexes 4: \(\text{C}_2\text{H}_2\text{Cl}_2\cdot 1.4\text{H}_2\text{O}\) (Fig. 2b) and 5: \(\text{C}_2\text{H}_2\text{Cl}_2\cdot 2\text{H}_2\text{O}\) (Fig. 51) have very similar structures; their capping oxide ions lie 0.308 and 0.313 Å above the \(\text{Mn}^{III}\) plane, respectively.

Solid-state, direct current (DC) magnetic susceptibility (\(\chi_M\)) data for dried 3–5 were collected in the temperature range 5.0–300 K in an applied field of 1 kG (0.1 T). The \(\chi_M T\) of 3 steadily increases from 13.01 cm\(^3\) mol\(^{-1}\) K at 300 K to a maximum of 19.39 cm\(^3\) mol\(^{-1}\) K at 30 K, before dropping to 17.41 cm\(^3\) mol\(^{-1}\) K at 5.00 K (Fig. 3). This behaviour is indicative of ferromagnetic exchange between the metal centers resulting in an \(S = 6\) ground state, with the low temperature decrease assigned to zero-field splitting. Zeeman effects and/or intermolecular antiferromagnetic interactions. The theoretical \(\chi_M T\) (spin-only, \(g = 2\)) for \(S = 6\) is 21 cm\(^3\) mol\(^{-1}\) K, close to the experimental value at 30.0 K. The data were fit to the theoretical expression for a \(\text{Mn}^{III}\) isosceles triangle [8]. The fit gave \(J = +14.1\) cm\(^{-1}\), \(J' = +3.8\) cm\(^{-1}\), \(g = 1.91\), and 0.9% paramagnetic impurity term, assumed to be \(\text{Mn}^{III}\). The corresponding fit values for 5 are \(J = +31.1\) cm\(^{-1}\), \(J' = +6.7\) cm\(^{-1}\), \(g = 1.91\), and 1.5% paramagnetic impurity term.

In order to confirm the spin ground states of the complexes, magnetization data were collected in the ranges 1–70 kG and 1.8–10.0 K, and these are plotted as reduced magnetization (\(M/N\mu_B\)) versus \(H/T\) for 3 in Fig. 4. For a cluster entirely populating the ground state and experiencing no zero-field splitting, the isofield lines should superimpose and saturate at a \(M/N\mu_B\) value equal to \(gS\). The data were fit by matrix diagonalization to a model that assumes only the ground state is populated, includes axial zero-field splitting (\(D_{S^2}\)) and the Zeeman interaction, and carries out a full powder average. The best fit (solid lines in Fig. 4) gave \(S = 6\), \(g = 1.92\) and \(D = -0.34\) cm\(^{-1}\). The corresponding data for the other two complexes are \(S = 6\), \(g = 1.93\), \(D = -0.34\) cm\(^{-1}\) for 4, and \(S = 6\), \(g = 1.91\), \(D = -0.36\) cm\(^{-1}\) for 5.

The magnitude of \(S\) and sign of \(D\) suggested these complexes might be SMMs, and AC susceptibility studies were therefore carried out in the 1.8–10.0 K range in a 3.5 G field oscillating at frequencies up to 500 Hz. Frequency-dependent out-of-phase AC susceptibility signals were seen

\[\text{Mn}^{III}\text{O}_2\text{CMe}\]
for the three complexes below 3 K (but no peaks were observed) along with a concomitant decrease in the in-phase signal, indicative of SMM behaviour. The data for 4 are shown in Fig. 5.

In order to probe the possible SMM behaviour further, single-crystal hysteresis loop and relaxation measurements were performed for 3·3CH₂Cl₂ and 5·2CH₂Cl₂ using a micro-SQUID apparatus [9]. Fig. 6 presents typical magnetization (M) versus applied DC field measurements at 0.04 K for 3·3CH₂Cl₂. A hysteresis loop, the diagnostic property of a magnet, was observed below 1 K, whose coercivity increases with decreasing temperature and increasing field sweep rate, as expected for the superparamagnetic-like behaviour of an SMM. The loops show the step-like features indicative of quantum tunneling of magnetization (QTM) between $M_s$ levels of the $S = 6$ ground state; the temperature-independent coercivity below 0.3 K indicates ground-state QTM. Magnetization decay versus time data and AC data to lower T were collected on 3·3CH₂Cl₂ and used to construct an Arrhenius plot (Fig. S2); fitting of the thermally activated region to the equation $\tau = \tau_0 \exp(U_{\text{eff}}/kT)$ gave $U_{\text{eff}} = 10.9$ K and $\tau_0 = 5.7 \times 10^{-8}$ s, where $U_{\text{eff}}$ is the effective magnetization relaxation barrier. Below 0.3 K, the relaxation is temperature-independent, consistent with relaxation by ground-state QTM. Slightly different SMM properties are observed for 5·2CH₂Cl₂ due to the presence of two crystallographically independent trinuclear cations in the crystal.⁴

An important question is the following: why are 3–5 ferromagnetically coupled and SMMs, whereas 1 and 2 (and many similar [Mn₃O(O₂CR)₆L₃]⁺ complexes) are antiferromagnetically coupled and are not SMMs? A probable contributory factor is that 3–5 have their central oxide ligand ~0.3 Å above the Mn₃ plane due to the tridentate ligand.

---

³ Details will be given in the full paper.
coordination of mpko\(^{-}\) or ppko\(^{-}\). In contrast, the oxide ion in 1, 2 and related species is coplanar with the three metal ions. This distortion from planarity in 3–5 weakens the antiferromagnetic contributions (via Mn\(^{III}\)\(d_p\)–O\(^2\)\(p\)–Mn\(^{III}\)\(d_p\) orbital overlap) to the observed exchange between two Mn\(^{III}\) ions, and the latter (which is the sum of ferro- and antiferromagnetic contributions) becomes ferromagnetic leading to \(S = 6\) ground states.

In summary, reactivity studies of the well known and well studied antiferromagnetically coupled [Mn\(_3\)O-(O\(_2\)CR)\(_6\)(py)\(_3\)](ClO\(_4\)) “starting materials” with 2-pyridyl oximes have led to a new family of triangular, oxide-centered, mixed carboxylate/2-pyridyloximate Mn(III) complexes that are ferromagnetically coupled with an \(S = 6\) ground state. Complexes 3–5 are SMMs, the first for 3d metal complexes with a triangular topology. Given this success, the use of 2-pyridyl oxime ligands in Mn carboxylate chemistry continues to be investigated.
