(Received 8 January 2013; published 13 May 2013)

The energy released in a magnetic material by reversing spins as they relax toward equilibrium can lead to a dynamical instability that ignites self-sustained rapid relaxation along a deflagration front that propagates at a constant subsonic speed. Using a trigger heat pulse and transverse and longitudinal magnetic fields, we investigate and control the crossover between thermally driven magnetic relaxation and magnetic deflagration in single crystals of Mn12-acetate.

DOI: 10.1103/PhysRevLett.110.207203

Raising the temperature of a flammable substance can ignite combustion, an exothermic reaction between a substance and an oxidizer that results in a chemically modified substance [1]. Deflagration is a self-sustained combustion that propagates at subsonic speed via thermal conduction; a locally burning substance increases the temperature of an adjacent unburned substance and ignites it. Deflagration is governed by local reactions and diffusion; reaction-diffusion systems are ubiquitous in nature—from cell growth to epidemics. The study of these nonlinear dynamical systems reveals rich phenomenology—including traveling waves, dissipative solitons [2], and self-organized patterns [3,4].

Magnetic relaxation is a reaction-diffusion process that can develop an instability and proceed as a magnetic deflagration. It can occur in a magnetic material prepared in a metastable spin configuration; here the reaction is the reversal of spins that releases Zeeman energy and the diffusion serves to transmit the energy to adjacent material. The phenomenon has been observed as fast magnetization jumps in molecular magnets [5,6], manganites [7], and intermetallic compounds [8]. In these systems, spins that are in a metastable state at low temperature slowly relax to a lower energy state releasing heat. In some circumstances, the heat cannot be compensated by thermal diffusion, resulting in an instability that gives rise to a front of rapidly reversing spins traveling through the sample at constant speed.

In this Letter we study the instability that leads to the ignition of magnetic deflagration in a thermally driven Mn12-acetate (hereafter Mn12-Ac) crystal. We explore how to control the crossover between slow magnetic relaxation and rapid, self-sustained magnetic deflagration using magnetic fields. Based on earlier work [9,10], we propose a simple model and perform numerical simulations that provide a good description of the experimental findings.

Mn12-Ac molecules are magnetically bistable [11] due to their high $S = 10$ spin and a magnetic anisotropy that provides a large energy barrier between spin-up and spin-down states [see Fig. 1(a)]. In the presence of an applied field $\mathbf{H} = (H_x, H_y)$ the simplest spin Hamiltonian has the form

$$\mathcal{H} = -D S_z^2 - g \mu_B H_x S_z - g \mu_B H_y S_z.$$  \hfill (1)

The first term defines the anisotropy barrier ($D S_z^2 \approx 65$ K) and the second and third terms specify the effect of the magnetic field applied parallel and perpendicular to the anisotropy axis. As shown in Fig. 1(a), the energy barrier between the metastable and the stable state is the activation energy $U$, and the energy released by the reversing spins is the Zeeman energy $\Delta E = 2 g \mu_B H_x S_z$. The transverse field $H_y$ reduces the activation energy and mixes eigenstates of $S_z$, leading to relaxation by quantum tunneling of magnetization, particularly at specific resonant values of the magnetic field [$H_z = k D / (g \mu_B) \approx 0.45 k T$, for integer $k$], corresponding to the crossings of energy levels with opposite spin projections. The longitudinal field $H_y$ biases the potential well also reducing the activation energy and increasing the relaxation rate.

The abrupt complete reversal of the magnetic moment of Mn12-Ac crystals was first reported by Paulsen and Park [12] and later shown to take the form of a propagating spin-reversal front [5]. Magnetic deflagration has been studied

FIG. 1. (a) Potential energy showing discrete energy levels of Mn12-Ac spin Hamiltonian [Eq. (1)]. (b) Schematic of the sample, Hall sensors, heater, and the directions of the applied magnetic fields.
by sweeping the magnetic field or by raising the crystal’s temperature. Thresholds for both temperature [13] and applied Zeeman fields [14] were found to be governed by quantum laws due to quantum tunneling of magnetization [15]. In the experiments reported below, the spin reversal was triggered using a heat pulse at one end of the sample.

Magnetic measurements were performed on three Mn$_{12}$-Ac single crystals of dimensions $\sim 0.3 \times 0.3 \times 2.1$ mm$^3$, $0.35 \times 0.35 \times 1.75$ mm$^3$, and $0.4 \times 0.4 \times 1.6$ mm$^3$ (samples A, B, and C, respectively). The samples were mounted on a one-dimensional array of Hall sensors (active area $20 \times 100$ $\mu$m$^2$ with 200 $\mu$m separation) [see Fig. 1(b)]. The three samples show essentially the same behavior; here we show data for sample C. Care was taken to align the sample and the Hall array (placed in the yz plane) relative to each other and relative to the magnet axes, as shown in Fig. 1(b). The Hall sensors detect the stray field $B_x$ [see the inset of Fig. 2(b)], which is maximum at the reversal front. Measurements were taken at 0.4 K in a $^3$He refrigerator in a three-dimensional vector superconducting magnet capable of producing bipolar bias fields up to 1 T and bipolar transverse fields up to 5 T. A 6 V, 30 ms pulse was applied to a thin film heater ($R = 1.32$ k$\Omega$ at 0.4 K) placed at one end of the sample to trigger spin reversal. A dc current of 20 $\mu$A was supplied to the array of Hall sensors and the signal from each sensor was amplified by a factor of 1000, filtered, and recorded by a data acquisition card.

At base temperature (0.4 K), the crystal was prepared in a fully magnetized state so that all the spins were aligned in one direction. A fixed $H_\perp$ was applied and $H_z$ was swept to the desired field and held. At this low temperature the spins are essentially blocked by the strong magnetic anisotropy of Mn$_{12}$-Ac, and relax slowly toward equilibrium. In this nonequilibrium state, we supplied a voltage pulse to the heater to increase the temperature at one end of the crystal to initiate spin reversal. The same pulse was used to trigger the data acquisition card to record the magnetization signals of different Hall sensors during 1 s. The procedure was repeated for several values of $H_z$ for a particular $H_\perp$.

Figure 2 shows the time evolution of the Hall sensor signals when a heat pulse is applied at $t = 0$ to sample C with the magnetization prepared as described above. Two cases are considered: a zero bias field [$H_z = 0$ T; see Fig. 2(a)], and a large bias field [$H_z = 0.61$ T; see Fig. 2(b)] for the same transverse field $H_\perp = 1.5$ T. A propagating spin-reversal region is observed in both cases; the change in magnetization always starts at the heater end and propagates towards the other end [from the 1st to the 6th sensor; see Fig. 1(b)]. As shown in Fig. 2, a peak in the signal corresponding to the enhancement of the local stray field ($B_x$) travels in the $z$ direction as the spin reversal propagates along the easy axis, ultimately reversing the magnetization of the entire crystal. The speed of propagation of the reversing spins can be determined from the time difference between pulses sensed by adjacent Hall sensors and their separation.

While the curves in Figs. 2(a) and 2(b) appear similar, closer inspection shows that the reversal processes at low and high bias are distinctly different. At zero (or low) bias, the time interval between adjacent peaks is relatively long and increases as the spin reversal propagates, indicating that the spin reversal is slowing down: the time to completion is on the order of 80 ms, and the peaks are fairly broad and broaden further as the reversal proceeds. Here the spin reversal propagates slowly and its speed decreases because the magnetization relaxes toward equilibrium following the heat pulse; its progress through the crystal is governed by thermal diffusivity.

By contrast, in the case of high bias shown in Fig. 2(b), the time between adjacent peaks is constant and on the order of 100 $\mu$s, corresponding to a constant speed of $v \sim 2$ m/s, consistent with the data measured by Suzuki et al. [5], the total time for reversal of the full magnetization of the crystal is of the order of 1 ms, and the peaks in Fig. 2(b) are substantially sharper and do not broaden as they travel. The constant speed in the case of a large $H_z$ is a signature of magnetic deflagration, a self-sustained process driven by the Zeeman energy released by the spins as they reverse.

We will now show that the crossover between these two regimes is surprisingly sharp. The speed of propagation of the spin-reversal fronts was determined from the time interval between maxima of the Hall sensors in the middle of the crystal (sensor 3 and 4) and their spatial separation.
Note that while the same speed is obtained using any pair of Hall sensors for large $H_z$, the speed varies from point to point at low $H_z$, and therefore between different Hall sensor pairs. As shown in Fig. 3, the speed of the spin-reversal front changes abruptly at a bias field that depends on the transverse field. For a given $H_\perp$, below a crossover bias field $H_{co}$ (for, e.g., $H_{co} = 0.25$ T for $H_\perp = 0$ T), the speed of propagation of the reversing spins is nearly independent of the bias field. However, above the crossover, the speed increases suddenly and depends strongly on the bias field. Figure 3(b), a magnification of Fig. 3(a) where the vertical scale has been expanded by a factor of 100, demonstrates this even more clearly.

The peaks in the speed at $H_z \sim 0.45$ T shown in Fig. 3(a) are a clear manifestation of the important influence of quantum mechanics on the dynamics of the system. These maxima are due to quantum tunneling at the resonant fields [15,16] whenever spin states on opposite sides of the anisotropy barrier have nearly the same energy. As noted earlier, tunneling enhances relaxation and effectively reduces the anisotropy barrier. As we increase $H_\perp$ we increase the tunnel splitting between levels, which results in a broadening of the resonance steps. A small peak can also be seen in Fig. 3(b) at the zero bias resonance. Note that the zero-field resonance is slightly shifted ($\sim 40$ mT) due to internal dipolar fields [17,18].

To better understand the crossover between the two regimes described above, we develop a simple model based on previous theory [9,10,19]. The reaction-diffusion system that describes the time evolution of the magnetization $m$ towards equilibrium $m_{eq}$ entails two processes: the Zeeman energy (i.e., heat) released into the sample by the spins as they reverse and the heat diffusion through the sample. The dynamical system of nonlinear partial differential equations reads

$$\dot{m} = -\Gamma (m - m_{eq}), \quad \dot{T} = \frac{m \Delta E}{C} + \nabla \cdot \kappa \nabla T. \quad (2)$$

Here $T$ is the temperature, $\kappa$ is the thermal diffusivity, $C$ is the heat capacity, and $\Gamma = \Gamma_0 \exp[-U(h_\perp, h_z)/(k_B T)]$ is the relaxation rate. For fields that are much smaller than the anisotropy field ($h_{a} = g \mu_B H_z/2DS \ll 1$) [20]

$$U(h_\perp, h_z) = DS^2 (1 - h_z)^2 \left[ 1 - 2h_\perp \frac{(1 - h_z^2)^{1/2}}{(1 - h_z)^2} \right]. \quad (3)$$

For some applied fields and initial conditions, the thermal diffusivity cannot compensate for the increase in temperature due to the Zeeman energy released by the reversing spins; the sample temperature then rapidly increases and a magnetic deflagration develops. To study the ignition of magnetic deflagration, we consider a system of spins blocked in a given metastable magnetic state, increase its temperature $T_s$ (e.g., from $T_s = 0.5$ to 6 K), and study the resulting nucleation process. Let us consider here for simplicity the temperature evolution in a nucleation volume, independent of coordinates,

$$\dot{T} = \frac{m \Delta E}{C} - 2\kappa (T - T_s)/R^2, \quad (4)$$

where $T$ is the temperature of the volume under study and $2R$ is the characteristic size of the nucleation volume. The negative term in Eq. (4) is linear with temperature while the reaction term increases exponentially with temperature $\{m \propto \exp[-U/(k_B T)]; \}$; there is thus a competition between these two terms and stationary solutions ($\dot{T} = 0$) correspond to temperatures when the dissipation equals the released energy.

As shown in the inset of Fig. 4, some magnetic field configurations $\{\mathbf{H} = (H_\perp, H_z)\}$ corresponding to small bias fields have stationary solutions (red dotted curve). As we vary $\mathbf{H}$ (i.e., we vary the relaxation rate $\dot{m}$), the
stationary points move closer to each other and eventually merge (green dashed curve) and disappear. When there is no stationary solution (blue solid line)—the temperature derivative is always positive leading to an instability—a magnetic deflagration may develop. The condition for the crystal to lose stability at a given \( T_s \) and \( H \) is \( \dot{T} > 0 \) and its crossover points are found by solving

\[
\dot{T} = 0, \quad \frac{\partial \dot{T}}{\partial T} = 0. \tag{5}
\]

At a given \( H_1 \), for \( H < H_{co} \), the energy released during the spin-reversing process is small (or even zero in the case of zero bias). The dynamics of the propagating front observed in this case [see Fig. 2(a)] are determined by the diffusion of the heat supplied by the heater pulse; this corresponds to a thermal regime. Here the reaction term in the full set of Eqs. (2) is negligible and the equation has a stable solution at a temperature close to the sample temperature. Neglecting the reaction term in the full set of Eqs. (2), it is clear that the heat diffuses and the magnetization locally follows the sample temperature.

For \( H_1 \to H_{co} \), the energy released by the reversing spins is large, the reaction term dominates over the diffusion term, and Eq. (4) displays an instability. In this Zeeman regime, the released energy drives the spin relaxation to a deflagration with steady propagation, where the speed of the propagating front of reversing spins strongly depends on both \( H_1 \) and \( H_1 \).

The sharp transition in propagation speed from thermal to Zeeman regimes as a function of the applied magnetic field is given by the condition in Eqs. (5). \( H_1 \) varies the activation barrier and does not change the released energy; it affects only \( \dot{m} \) in the reaction term. \( H_1 \) affects both \( \dot{m} \) and \( \Delta E \).

In the main panel of Fig. 4, we plot the boundaries that separate the thermal regime from the Zeeman regime derived from Eq. (5) together with the experimental points (blue dots) obtained from Fig. 3. For fields above the boundary curve, the reaction term dominates and the crystal develops a magnetic deflagration; below the curves, thermal diffusion dominates and the spins evolve toward equilibrium through slow thermal relaxation. For the calculations we have taken as free parameters the temperature \( T_s \) to which we heat one end of the sample, and the combination of thermal diffusivity and nucleation size \( \kappa/R^2 \). Using a heat capacity close to the measured value \( C/k_B = 1 \) [i.e., \( C = 8.3 \text{ J/(mol K)} \)] [21], and bounding \( 2R \) by the smallest sample dimension of 400 \( \mu \text{m} \), a good qualitative fit was obtained for \( T_s = 6 \text{ K} \) and \( \kappa = 1 \times 10^{-4} \text{ m}^2/\text{s} \), which agrees well with previously used values [22]. It is important to note that equally good fits can be obtained using different combinations of parameters.

The smoothness and reproducibility of the data in Fig. 3 suggest that the appearance of instabilities leading to a magnetic deflagration when raising the temperature of the \( \text{Mn}_{12} \)-Ac crystal is a well controlled process. Once the crystal is in the Zeeman regime the speed of the magnetic deflagration can be controlled by the strength of the applied field. Additionally, equal propagation speeds are obtained for different combinations of applied fields, as seen in Fig. 3 where a particular speed can be seen to correspond to different magnetic field configurations. Larger bias fields would produce larger amounts of heat released and higher temperatures for the overall process, while large transverse fields that speed up the process by the same amount would heat the sample much less. This illustrates the strongly anisotropic nature of deflagration in \( \text{Mn}_{12} \)-Ac. The anisotropic properties of magnetic deflagration have been investigated both experimentally [14,23] and theoretically [24].

To summarize, we have measured the dynamics of spin-reversal fronts in \( \text{Mn}_{12} \)-Ac crystals in the presence of both bias and transverse magnetic fields. We have shown how these applied fields can be used to control an instability that separates slow magnetic relaxation from rapid, selfsustained magnetic deflagration.

We have also expanded the range of conditions under which magnetic deflagration has been observed, particularly to the case of small bias fields, which corresponds to small energy release in the deflagration process. This is a particularly interesting limit in which instabilities in the front are predicted to occur, such as pattern formation and oscillations of the propagating front [25]. In the presence of large transverse fields, where quantum tunneling dominates over thermal effects, the instabilities in the magnetization dynamics could lead to a deflagration-to-detonation transition [27,28] and may result in supersonic fronts [26]. The present experiments thus provide opportunities to study—in a nondestructive manner—a large variety of instabilities in magnetic systems.
